Introduction
Since the introduction of Magnetic resonance imaging (MRI), the use of high-field-strength MRI in musculoskeletal imaging has become more common. The benefits of MRI are shown as a desirable method in the diagnostics of occult scaphoid fracture in particular the visualization of bone bruise (1). Different fat suppression sequences with different backgrounds can detect the presence of bone bruise e.g. Short tau inversion recovery (STIR), Spectral fat saturation (FAT SAT), Hybrid, Fat – water separation and Dixon (2). However, a majority of published articles describes the standard method for musculoskeletal MRI fat suppression comprising the STIR or T2 FAT SAT sequence, but no unified guidelines is described. Sufficient choice of sequence may result in consequences for the patient as pseudoarthrosis, osteoarthritis, avascular necrosis and chronic wrist pain, if a fracture remains undiagnosed (3,4).

The importance of identifying and locating bone bruise is essential in relation to fracture but in addition, bone bruise may also be the only pathological finding explaining the patients symptoms of pain. This highlights the importance of the technicians awareness of the advantages and disadvantages affiliated with the various sequences (3,4).

Methods
In the period March 2014 until January 2015 195 patients underwent MRI examinations of the scaphoid bone. Fifty-one patients (average: 19 years, M: 40, F:11) met the inclusion criteria's.

Inclusion criteria for acute MRI scan of scaphoid bone
- Relevant trauma less than 2 weeks
- Negative X ray of scaphoid bone
- Positive clinical finding
- Age > 10 years (> 3 mm between the scaphoid bone and the lunate bone)
- Bone bruise on coronal STIR and sagittal T2 FAT SAT
- Motion artifact free sagittal T2 FAT SAT and STIR images

The fifty-one recruited patients underwent an additional sagittal STIR Scan sequence. The sagittal T2 FAT SAT and STIR were then compared and evaluated.

Image evaluation
Bone bruise and image quality assessment included three methods:
1. Comparison of the area
2. Comparison of CNR
3. Comparison of bone bruise image contrast

The image material was continually and independently assessed by all three readers blinded to each other’s results. All measurements were performed on the same slice and the same PACS monitor, to ensure a identical and comparable image quality.

Data were subsequently analyzed by unpaired Student’s-t test and Pearson correlation analysis (PCC).

Image contrast = (Sa–Sb)/(Sa+Sb) (6)
Sb = Signal intensity of bone bruise
Sa = Signal intensity of normal bone
SIR = SD of signal intensity outside the image

Results
There was no significant variation relative to the area of the bone bruise (p > 0.005) and the CNR (p > 0.005).

An interchangeably usage of the two sequences was found acceptable for the diagnostic (> 1 T) if the protocol is properly composed. However, the T2 FAT SAT sequence provides a image contrast superior to the STIR sequence.

Conclusions
An interchangeably usage of the two sequences was found acceptable for the diagnostic (> 1 T) if the protocol is properly composed. However, the T2 FAT SAT sequence provides a image contrast superior to the STIR sequence.
